# AGE OR TIME-TO-DEATH WHAT DRIVES HEALTH CARE EXPENDITURES? PANEL DATA EVIDENCE FROM THE OECD COUNTRIES* 

Maciej Lis ${ }^{\dagger \dagger}$

#### Abstract

Over the last 50 years, the most important engines of growth in aggregate health care expenditures (HCEs) in the OECD countries have been growth in income, technological progress in medicine, and the interaction of these two trends with institutional settings. Accelerated ageing is also expected to fuel the increase in HCEs in the future. Understanding the interaction of these growth factors with age is crucial for understanding the impact of ageing on health care expenditures. We propose a non-linear framework for testing the dynamics of the interaction of the growth in HCEs with the age structure. This framework utilises the micro and the cohort evidence from other studies on the shape of HCEs and time-to-death. We have found that the growth in health care expenditures in recent decades in 26 OECD countries was concentrated on close-todeath expenditures. The growth rates of close-to-death HCEs were twice as high as the growth rates of expenditures more distant from death. However, we were unable to identify a clear pattern in the dynamics of age.

Keywords: aggregate healthcare expenditure, ageing, red herring, death related costs, panel models

JEL Codes: H51, I12, I18, J14

## 1 Introduction

In recent decades, health care expenditures (HCEs) have been rising more quickly than GDP in all OECD countries. This growth in HCEs has been fuelled by technological progress in medicine and rising incomes The accelerating ageing process is expected to create additional pressure on the growth in HCEs in the near future. As these expenditures are largely publicly financed, the rapid increase in HCEs has led to concerns being raised about the stability of public finances if current trends continue. Therefore, understanding the role of ageing in shaping HCEs is important not only for scholars, but also for public policy-makers responsible for planning health budgets and managing future budgetary pressures. In the current paper, we examine the stability of the age profiles of HCEs in OECD countries.

The hypothesis that rising incomes and technological progress are the main drivers of the rise in HCEs has been confirmed by wide empirical evidence. The role of technological progress in shaping HCEs was posited by Newhouse (Newhouse 1992), and has been confirmed for the US (Chernew et al. 1998 Okunade and Murthy. 2002 Smith et al. 2009 Di Matteo 2005), France (Dormont et al., 2006), Germany (Breyer and Felder 2006), and the OECD countries (Oliveira Martins and de la Maisonneuve 2006). In particular, Reinhardt (2003), who reviewed the evidence from the US, Canada, and Australia, pointed out that agespecific health care expenditures are a rather poor proxy for the dynamics of aggregate HCEs. HCEs are influenced by other factors, such as technological progress and income. Technological progress fuels HCEs because it delivers large numbers of new and expensive medicines and treatments, but relatively few costcurbing innovations in process (Weisbrod 1991).

Public and private health insurance serves as a vehicle for transferring income from those in good health to those in bad health. This aspect of health insurance has been raised in the discussion of ex post moral hazard (Pauly, 1968, Feldstein, 1973 Nyman, 2006; Manning and Marquis, 2001). If incomes are rising but the options for curing less severe health problems change very little, the scale of this transfer should be magnified. Given that time-to-death is a better predictor of bad health status than age, we would expect to find that rising incomes widen the gap in HCEs between survivors and decedents, (1) rather than between the young and the old (2).

There are a few methodological approaches that can be used to project the impact of ageing on HCEs. The first one is to calculate the age profiles of HCEs with the assumption that they are constant over time. Within such a framework, the impact of the changing population structure on HCEs is straightforward. The second approach is enriched by introducing time-to-death as an additional dimension of the profiles. Recent evidence (van Baal and Wong 2012) shows, however, that the age and the time-to-death profiles of HCEs are not stable over time. Therefore, both 'static' approaches can be misleading. In particular, technological innovations and the steady growth in income do not affect all health statuses equally, but tend to favour some more than others. Understanding the interactions of technological progress and increases in income with age and time-to-death are crucial for understanding the impact of ageing on health care expenditures.

Some empirical insights into the dynamics of the age structure of HCEs have been provided by a few studies that utilised detailed, country-specific datasets (van Baal and Wong, 2012, Zweifel et al. 2005, Gregersen 2014 Sato and Fushimi 2009 Lis 2015b). We propose models that make use of the evidence from micro or cohort data, but that can be estimated using aggregate data. In particular, we propose aggregate measures of time-to-death. We utilise the empirical evidence on the profiles of health care expenditures in estimating the models with macro data.

Because ageing is expected to have large impact on HCEs, academic and policy discussions of HCEs have focused on the determinants of the age profiles of HCEs. Przywara et al. (2010) generated stylised facts on the age profiles from nine EU countries, which were also confirmed for Japan by Sato and Fushimi (2009). The health care expenditure profiles share the following features:

- HCEs are high for new-borns, then decline, and then start rising when people are in their forties. People who are in their eighties have HCE levels that are 5-10 times higher than people in their thirties.
- The gap between expenditures for survivors and for decedents is widest among young people. The gap is nearly 40 times at age 10 , and narrows steadily with age, to $1-3$ times at age 90 .

In addition, Lis (2015b) has shown for Poland that this pattern is fuelled by age-related increases in the share of the population who spend time in the hospital. These facts create the backdrop for a discussion that focuses on two questions: What is the role of time-to-death in shaping health care expenditures? And, what are the dynamics of the age and the time-to-death HCE profiles? Zweifel et al. (1999, 2004) addressed the first question by proposing the 'red herring' hypothesis. The main implication of the hypothesis is that due to the concentration of HCEs before death, the effect of ageing on aggregate spending may even be neutral. This hypothesis was later discussed and tested empirically inter alia by Meara et al. (2004); Werblow et al. (2007); Shang and Goldman (2008); Wong et al. (2011). Here, however, we focus on the 'red herring' in a dynamic setting: i.e., how the age and the time-to-death profiles of HCEs evolve in the long run, as technological progress and rising incomes play increasingly large roles. A discussion of the origins of these questions in relation to the theories regarding the demand for health care expenditures is presented in detail by Melberg (2014).

There are some important insights into the dynamics of the age profiles of HCEs from selected countries. Buchner and Wasem (2006) formulated the hypothesis of steepening; i.e., that because most technological changes in medicine are designed to help people in bad health, expenditures on older people will rise more quickly than expenditures on younger people. They found evidence of the steepening of HCEs in Germany in the years 1979-1996. In particular, HCEs on people aged $65+$ rose $50-80 \%$ increased more quickly than expenditures on younger people. Gregersen (2014) found similar evidence for Norway, when infants aged zero were excluded. His analysis also showed that mortality interacts with time trends in HCEs, and thus confirmed that death-related expenditures had been rising faster than expenditures unrelated to death.

The dependence of HCEs on time-to-death varies with both age and time. Recent evidence has suggested that the static effect of time-to-death on HCEs is offset by the dynamics. As death-related HCEs rise faster than other expenditures, ageing puts considerable pressure on HCEs. Breyer et al. (2015), using microdata from the German socio-economic panel, have shown that age, mortality, and survival rates all have positive effects on health care expenditures. Similarly, van Baal and Wong (2012), using age- and genderspecific health care expenditures for Netherlands in 1981-2007, proved that models with and without time-to-death generated very similar forecasts of future health care expenditures, primarily because HCEs in the last year of life rise more quickly than in other years. Taking a slightly different perspective, Zweifel et al. (2005) found evidence that extending life expectancy causes health care expenditures to rise because extra care is needed in the additional years of life. They called this phenomenon the Sisyphus effect: the more resources that are spent on saving lives, the more resources that are needed for survivors. They used the OECD aggregate data from 1970-2000.

Our approach for identifying the dynamics of the profiles of health care expenditures builds on the work of Buchner and Wasem (2006), van Baal and Wong (2012) and Zweifel et al. (2005). We developed a framework
for tracing changes in HCE profiles related to age and time-to-death with the use of aggregate data. We therefore decided to merge the dataset on mortality from the Human Mortality Database with the data on aggregate health care expenditures in OECD countries.

## 2 Data

The dataset on the detailed population structure and the age-specific death rates has been merged with the data on aggregate, country-level HCEs. First, the Human Morality Databas $\mathbb{}^{1}$ provided us with exact data on mortality and the population by one-year age groups for 37 countries, stretching back to the $19^{\text {th }}$ century for some countries. Using mortality and population data we were able to calculate the whole distribution of time-to-death for each age group. These data were merged with the OECD data on aggregate health care expenditures. After merging and cleaning the data, we ended up with 26 countries and 876 observations. The minimal number of observations was 18 for Germany and Hungary, and the maximum number of observations was 40 for Iceland. The panel was unbalanced, with two-thirds of the countries covered for 1970-1990, and the full sample covered for 1992-2006.

Table 1: Dynamics of HCEs and population in the sample

|  | sample |  | average annual growth rate of |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| country | first | last | HCE | population |  |  |
|  | year | year | USD 2000 PPP | total | $65+\mid<3$ years to death |  |
| Australia | 1971 | 2007 | 4.7 | 1.3 | 2.6 | 0.8 |
| Austria | 1970 | 2008 | 4.5 | 0.3 | 0.8 | -0.6 |
| Belgium | 1970 | 2008 | 4.9 | 0.3 | 0.9 | -0.3 |
| Canada | 1970 | 2008 | 4.1 | 1.2 | 2.6 | 1.2 |
| Czech Republic | 1990 | 2008 | 4.3 | 0.0 | 0.9 | -1.0 |
| Denmark | 1971 | 2007 | 2.7 | 0.3 | 0.9 | 0.4 |
| Finland | 1970 | 2008 | 4.0 | 0.4 | 2.0 | 0.3 |
| France | 1970 | 2008 | 4.4 | 0.5 | 1.2 | 0.0 |
| Germany | 1990 | 2008 | 3.5 | 0.2 | 1.9 | -0.4 |
| Hungary | 1991 | 2008 | 2.9 | -0.2 | 0.9 | -0.5 |
| Iceland | 1970 | 2009 | 5.4 | 1.1 | 1.9 | 0.9 |
| Ireland | 1970 | 2008 | 6.3 | 1.0 | 1.0 | -0.3 |
| Israel | 1983 | 2008 | 4.1 | 2.4 | 2.7 | 1.5 |
| Italy | 1988 | 2009 | 2.3 | 0.3 | 2.0 | 0.4 |
| Japan | 1970 | 2007 | 4.4 | 0.6 | 3.5 | 1.3 |
| Luxembourg | 1970 | 2006 | 6.4 | 0.8 | 1.3 | -0.2 |
| Netherlands | 1972 | 2008 | 3.6 | 0.6 | 1.6 | 0.5 |
| New Zealand | 1970 | 2008 | 4.0 | 1.1 | 2.1 | 0.5 |
| Norway | 1970 | 2008 | 5.0 | 0.5 | 0.9 | 0.2 |
| Poland | 1990 | 2008 | 6.0 | 0.0 | 1.7 | 0.0 |
| Portugal | 1970 | 2006 | 6.9 | 0.5 | 2.2 | 0.5 |
| Spain | 1970 | 2008 | 5.5 | 0.8 | 2.2 | 0.9 |
| Sweden | 1970 | 2008 | 3.0 | 0.4 | 1.0 | 0.3 |
| Switzerland | 1970 | 2008 | 3.4 | 0.5 | 1.5 | 0.2 |
| UK | 1970 | 2008 | 4.1 | 0.3 | 0.8 | -0.3 |
| USA | 1970 | 2008 | 5.1 | 1.1 | 1.7 | 0.7 |

Source: Own calculations based on OECD data on HCEs and on population data from Human Mortality Database.

[^1]For the purposes of comparability, the real (in 2000 US \$) health care expenditures and the whole population are normalised by dividing by the level from 2000 for every country. The dynamics of the HCEs and the population in the sample are presented in Table 1 which also presents the dynamics of the population and the subpopulations within each country.

The first surprising finding is that the USA is not the first but the sixth in the dynamics of aggregate HCEs. The United States is overtaken by countries with a high degree of convergence in incomes and low HCE starting levels: i.e., by Ireland, Spain, Portugal, and Poland. The population dynamics are much more closely correlated with the HCE dynamics (.25) than with the dynamics of those older than age 65 (.09) and of those within three years of death (.01). Of the countries in the sample, Hungary is the only one that did not experience population growth (shorter time period), and all of the countries experienced an increase in the number of people over age 64 . Despite the common pattern of higher dynamics among the older population, mortality was declining even faster, and eight countries showed negative changes in the number of people within three years of death.

## 3 Methods

Aggregate HCEs is the sum of the HCEs in the subpopulations, distinguished by age and proximity to death. Formally:

$$
\begin{equation*}
H=\sum_{a} \sum_{t} h_{a, t} n_{a, t} \tag{1}
\end{equation*}
$$

where $a \in 5,10, . ., 90$ is the index of age, $t \in 0,1,2, . ., 10$ is the index of years remaining to death, $h_{a, t}$ is average health care expenditures among individuals aged $a$ who will die in $t$ years, and $n_{a, t}$ is the size of the population group of age $a$ and within $t$ years of death.

Detailed HCEs ( $h_{a, t}$ ) are unobservable, but the sizes of the age groups $n_{a}$ are available directly from the data, and the breakdown for the proximity of death $n_{a, t}$ could be calculated using the mortality data, observing that:

$$
\begin{equation*}
\mathfrak{n}_{\mathrm{a}, \mathrm{t}}=\prod_{\mathfrak{i}=0}^{\mathrm{t}-1}\left[1-\mathfrak{m}_{\mathrm{a}+\mathrm{i}}\right] \mathrm{m}_{\mathrm{a}+\mathrm{t}} \mathfrak{n}_{\mathrm{a}} \tag{2}
\end{equation*}
$$

where $m_{a}$ is the mortality rate at age $a$.
Based on the evidence from a few countries (Przywara et al. 2010 Sato and Fushimi 2009 Lis 2015b), proving that HCEs per survivor rise with age whereas HCEs per decedent drop with age, and the "year method" of Buchner and Wasem (2006), we aggregate the population into four subpopulations:

- younger than $A$ and dying within $T_{g}$ years,
- younger than $A$ and living longer than $T_{g}$ years,
- older than $A$ and dying within $T_{l}$ years,
- older than $A$ and living longer than $T_{l}$ years.

Therefore, we get:

$$
\begin{equation*}
H=\sum_{a<A}\left[\sum_{t<T_{9}}\left(h_{a, t} n_{a, t}\right)+\sum_{t \geq T_{g}}\left(h_{a, t} n_{a, t}\right)\right]+\sum_{a \geq A}\left[\sum_{t<T_{l}}\left(h_{a, t} n_{a, t}\right)+\sum_{t \geq T_{l}}\left(h_{a, t} n_{a, t}\right)\right] \tag{3}
\end{equation*}
$$

After rearranging and averaging HCEs in each of the four groups, we get:

$$
\begin{array}{r}
H=\sum_{a<A} \sum_{t<T_{g}}\left(h_{a, t} n_{a, t} t\right)+\sum_{a<A} \sum_{t \geq T_{g}}\left(h_{a, t} n_{a, t}\right)+\sum_{a \geq A} \sum_{t<T_{l}}\left(h_{a, t} n_{a, t}\right)+\sum_{a \geq A} \sum_{t \geq T_{l}}\left(h_{a, t} n_{a, t}\right) \\
H=h_{1} \sum_{a<A} \sum_{t<T_{g}}\left(n_{a, t}\right)+h_{2} \sum_{a<A} \sum_{t \geq T_{g}}\left(n_{a, t}\right)+h_{3} \sum_{a \geq A} \sum_{t<T_{l}}\left(n_{a, t}\right)+h_{4} \sum_{a \geq A} \sum_{t \geq T_{l}}\left(n_{a, t}\right) \tag{5}
\end{array}
$$

And, finally, we substitute the sums in order to get:

$$
\begin{equation*}
H=h_{1} n_{1}+h_{2} n_{2}+h_{3} n_{1}+h_{4} n_{1} \tag{6}
\end{equation*}
$$

The above identity holds for every country (c) and every year ( y ). Therefore:

In the data on aggregate health care expenditures and population structure $\left(\forall_{i \in(1,2,3,4)} \mathfrak{n}_{\mathfrak{i}}\right)$ the above relationship is unidentified. We are, however, interested in the average rate of growth of $h_{1}, h_{2}, h_{3}$, andh $h_{4}$. Therefore, we propose the following equation of the constant rate of growth among countries and across time, except for the initial HCEs in each subpopulation and country:

$$
\begin{equation*}
h_{i}^{c, y}=h_{i}^{c, y_{0}}\left(1+\alpha_{i}\right)^{\left(y-y_{0}\right)} \tag{8}
\end{equation*}
$$

We then insert them into the equation 6 and get an indefinable form:

$$
\begin{equation*}
H^{c, y}=\sum_{i=1}^{4} h_{i}^{c}{ }_{i}^{c, y_{0}}\left(1+\alpha_{i}\right)^{\left(y-y_{0}\right)} n_{i}^{c, y}+\epsilon^{c, y} \tag{9}
\end{equation*}
$$

Due to the high degree of correlation among $n_{i}$ and the country-specific effects, the differenced form is more robust than the model with levels. For a country $c$ and $h_{i}$ we get:

$$
\begin{gather*}
h_{i}^{c, y+1} n_{i}^{c, y+1}-h_{i}^{c, y} n_{i}^{c, y}= \\
\left(1+\alpha_{i}^{c}\right) h_{i}^{c, y} n_{i}^{c, y+1}-h_{i}^{c, y} n_{i}^{c, y}= \\
h_{i}^{c, y}\left(\left(1+\alpha_{i}^{c}\right) n_{i}^{c, y+1}-n_{i}^{c, y}\right)=  \tag{10}\\
h_{i}^{c, y}\left(\left(n_{i}^{c, y+1}-n_{i}^{c, y}\right)+\alpha_{i}^{c} n_{i}^{c, y+1}\right)= \\
h_{i}^{c, y}\left(\Delta n_{i}^{c, y}+\alpha_{i}^{c} n_{i}^{c, y+1}\right)
\end{gather*}
$$

And the transformed Equation 11 becomes :

$$
\begin{equation*}
\Delta H^{c, y}=\sum_{i=1}^{4} h_{i}^{c, y_{0}}\left(1+\alpha_{i}\right)^{\left(y-y_{0}\right)}\left(\Delta n_{i}^{c, y}+\alpha_{i} n_{i}^{c, y+1}\right) \quad+\quad \epsilon^{c, y} \tag{11}
\end{equation*}
$$

We then make the additional assumption that the HCEs are positive:

$$
\begin{equation*}
\forall_{i \in\{1,2,3,4\}}: h_{i}>0 \tag{12}
\end{equation*}
$$

We end up with the first model to be estimated (Equations: 11, ,12):

$$
\begin{gather*}
\Delta H^{\mathfrak{c}, y}=\sum_{i=1}^{4} h_{i}^{c, y_{0}}\left(1+\alpha_{i}\right)^{\left(y-y_{0}\right)}\left(\Delta n_{i}^{c, y}+\alpha_{i} n_{i}^{c}, y+1\right. \tag{13}
\end{gather*}+\epsilon^{\mathfrak{c}, y}
$$

We also provide two simpler models with only a breakdown by age or time-to-death:

$$
\begin{align*}
& H=h_{1 a} \sum_{a<A} \sum_{t}\left(n_{a, t}\right)+h_{2 a} \sum_{a \geq A} \sum_{t}\left(n_{a, t}\right)  \tag{14}\\
& H=h_{1 \text { ttd }} \sum_{a \in A} \sum_{t<T_{g}}\left(n_{a, t}\right)+h_{2 t t d} \sum_{a \in \mathcal{A}} \sum_{t \geq T_{g}}\left(n_{a, t}\right) \tag{15}
\end{align*}
$$

The model is subsequently transformed into the differenced form, as previously (see Equation: 11). Finally, we estimate the full model (Equation: 11) in the same way as the two simpler models (Equations: 14 and 15 ) with condition 12 These models are estimated for every $A \in 5,10, . ., 85,90$ and $T_{g}=T_{l} \in 0,1,2, \ldots, 10$. The results for the selected break-downs are reported.

We also check another empirical strategy, in line with evidence provided by (Przywara et al. 2010, Lis, 2015a). Starting with Equation 1 , we assume that, on average, HCEs rise exponentially before death. We therefore assume:

$$
\begin{gather*}
\forall_{\mathrm{a}, \mathrm{t}<\mathrm{T}_{\mathrm{b}}}: \mathrm{h}_{\mathrm{a}, \mathrm{t}}=\mathrm{h}_{\mathrm{a}+\mathrm{t}, \mathrm{o}} \beta^{\mathrm{t}}  \tag{16}\\
\forall_{\mathrm{a}, \mathrm{t} \geq \mathrm{T}_{\mathrm{b}}}: \mathrm{h}_{\mathrm{a}, \mathrm{t}}=\gamma \tag{17}
\end{gather*}
$$

Combining Equations 9 and 17

$$
\begin{equation*}
H=\sum_{a}\left[\sum_{t<T_{b}} h_{a+t, o} \beta^{t} n_{a, t}+\sum_{t \geq T_{b}} \gamma n_{a, t}\right] \tag{18}
\end{equation*}
$$

In order to secure the smoothness of health care costs at the age of $a-T_{b}$, we add a constraint:

$$
\begin{equation*}
h_{a+T_{b}, 0} \beta^{T_{b}}=\gamma \tag{19}
\end{equation*}
$$

We can therefore eliminate $\beta$ :

$$
\begin{equation*}
\beta=\left(\frac{\gamma}{h_{a+T_{b}, 0}}\right)^{\frac{1}{\tau_{\mathrm{r}}}} \tag{20}
\end{equation*}
$$

We also need the restrictions for the $h_{a, 0}$ on the support of ages $0, \ldots, 110$. Based on the evidence from Poland on the profiles of health care expenditures in the last year of life, we have chosen the double sigmoid function:

$$
\begin{equation*}
h_{a+t, 0}=\eta_{1}\left[\tanh \left(\frac{(a+t)-\eta_{2}}{\eta_{3}}\right)-\tanh \left(\frac{(a+t)-\eta_{4}}{\eta_{5}}\right)\right]+\eta_{6} \tag{21}
\end{equation*}
$$

The example of the double sigmoid function is presented in Figure 17 It allows for a flexible decline in health care expenditures with age.

Figure 1: Double sigmoid function

Remarks: Parameters of the function: $\eta_{1}=.25, \eta_{2}=10, \eta_{3}=-5, \eta_{4}=67, \eta_{5}=15, \eta_{6}=.7$

In order to account for heterogeneity across countries, we allow countries to have specific starting points for HCEs unrelated to death $\gamma^{c}$, the costs incurred by decedents $\left(\eta_{6}^{c}\right)$, the slope of the age profiles of costs incurred by decedents $\left(\eta_{1}^{c}\right)$, and the ages of two turning points in the $h_{a, 0}$ profile $\left(\eta_{2}^{c}, \eta_{4}^{c}\right)$. We assume that the rates of change of these parameters are constant across countries and years ( $\varphi_{\gamma}, \varphi_{1}, \varphi_{2}, \varphi_{3}, \varphi_{4}$ ). Furthermore, another two parameters $\eta_{3}, \eta_{5}$ are assumed to be constant across years and countries. Additionally, we add the constraint of positive costs, and another constraint to ensure that the costs of decedents
are not lower than those of survivors. Therefore, the complete model is as follows:

$$
\begin{align*}
& H^{c, y}=\sum_{a}\left[\sum_{t<T_{b}} h_{a+t, 0}^{c, y}\left(\beta^{c}\right)^{t} n_{a, t}^{c, y}+\sum_{t \geq T_{b}} \gamma^{c, y} n_{a, t}\right]+\epsilon^{c, y} \\
& h_{a+t, 0}^{c, y}=\eta_{1}^{c}\left[\tanh \left(\frac{(a+t)-\eta_{2}^{c}}{\eta_{3}^{c}}\right)-\tanh \left(\frac{(a+t)-\eta_{4}^{c}}{\eta_{5}^{c}}\right)\right]+\eta_{6}^{c} \\
& \forall_{i \in 1,2,4,6}: \eta_{i}^{c}=\left(1+\varphi_{i}\right)^{\left(y-y_{0}\right)} \kappa_{i}^{c}{ }^{c} y_{0} \\
& \gamma^{\mathrm{c}, \mathrm{y}}=\left(1+\varphi_{\gamma}\right)^{\left(y-y_{0}\right)} \kappa_{\gamma}^{\mathrm{c}, \boldsymbol{y}_{0}} \\
& \beta^{c, y}=\left(\frac{\gamma^{c, y}}{h_{a+T_{b}, 0}^{c}}\right)^{\frac{1}{T_{b}}}  \tag{22}\\
& \gamma^{\mathrm{c}, \mathrm{y}}>0 \\
& \eta_{1}^{\mathrm{c}, \mathrm{y}}>0 \\
& \eta_{6}^{\mathrm{c}, y}>2 \eta_{1}^{\mathrm{c}, \mathrm{y}}+\gamma^{\mathrm{c}, \mathrm{y}} \\
& \epsilon^{\mathfrak{c}, \boldsymbol{y}} \sim \mathcal{N}
\end{align*}
$$

The final sample contains 876 observations in levels and 844 observations in differences from 26 countries. We end up with $5 \mathrm{~N}=130$ parameters to cover the heterogeneity of countries and 7 parameters that are constant across countries and years. Two of these seven parameters - the growth rate of costs in the last year of life $\left(\varphi_{6}\right)$ and of the costs unrelated to death $\left(\varphi_{\gamma}\right)$ are crucial for the findings.

All of the models (Equations: 13,1415 and 22) have been estimated as non-linear least squares, which are equivalent to the maximal likelihood with the residuals normally distributed. The optimisation gradient algorithm ${ }^{2}$ has been modified in order to take into account the panel nature of the data. After the algorithm converged, the resulting parameters of starting values at $t_{0}$ were rescaled in order to satisfy the equality of the predicted and the actual mean values of HCEs for each country. The algorithm was restarted with the new starting values. The iteration was continued until convergence was achieved.

## 4 Results

The models deliver mixed results. The key parameters describing the dynamics of HCEs within different models and breakdowns are presented in Table 2. The complete statistics of the models can be found in the appendix. The first model, in which the population was broken down into four groups based on age and time-to-death, shows very high dynamics in HCEs for young people who are close to death. Specifically, $\alpha_{1}$ finds that the annual growth rate is $30 \%$ higher for people under age 10 , and is $20 \%$ higher for people under age 50 who are close to death. For young people who are more distant from death ( $\alpha_{2}$ ), we observe an average pace of growth in HCEs; i.e., of 2-4\% a year. The results for older people ( $\alpha_{3}$ and $\alpha_{4}$ ) are unclear. The coefficients $\alpha_{3}$ and $\alpha_{4}$ show that while the dynamics increase with age, they are insignificantly different from zero. This might be due to increasing variation among smaller subpopulations and high levels of heterogeneity among countries. Moreover, the finding that there is a much smaller difference between the dynamics of survivors and decedents at older than at younger ages is in line with the age profiles of HCEs found by Gregersen (2014); Lis (2015b).

The results from the second model with the breakdown of the population into two subpopulations only based on age thresholds suggest that HCEs rise more quickly among young people ( $\alpha_{1}$ ), but with much more variation than in the previous model. However, the variation found in the parameters of the models does not support the robustness of this finding. Therefore, the models do not provide any strong evidence regarding the age structure of the dynamics of HCEs. We conclude that, according to our results, age
structure has a rather modest impact on the dynamics of HCEs.
By contrast, the model with the breakdown of the population into two subpopulations based on time-todeath generates clear results. The closer people are to death, the faster their health care expenditures rise. For people within three years of death, HCEs increase 2-3 times faster $\left(\alpha_{1}\right)$ than for those who are further from death $\left(\alpha_{2}\right)$. The differences in the dynamics in HCEs between for people within 1-5 years of death and people who are further from death are statistically significant. For the threshold of 10 years before death, the differences in the dynamics fade. This gradual decline in the differences in the dynamics as people move further away from death supports the robustness of the findings. On the one hand, this pattern supports the view that time-to-death influences the dynamics of HCEs much more than age; while on the other, it shows that the reduction in mortality due to HCEs is also an important factor.

The model with the full profile of age and time-to-death strongly supports the result that the dynamics of HCEs are concentrated among those who are close to death. No matter what distance from death we consider (1-10 years), the dynamics for those who are further from death increases around $3 \%-4 \%$ a year $\left(\varphi_{\gamma}\right)$, whereas the dynamics for those who are closer to death rises around 1 percentage point faster $\left(\varphi_{6}\right.$, see Eq. 22). Additionally, the age profile of health care expenditures in the last year of life steepens, as $\varphi_{1}$ is significantly larger than zero in any specification. This finding strongly supports the previous result that the rise in HCEs is concentrated among people who are close to death, and particularly among younger people in bad health. It also supports the view that higher HCEs are associated with lower mortality.

## 5 Discussion

We have shown that in OECD countries rising health care expenditures tend to be concentrated among people who are close to death, an indicator that is a good proxy for people who are in very bad health. This result can be attributed to at least one of three processes, but we cannot distinguish between them. First, technological progress is concentrated on finding cures for very severe health conditions. In other words, the more serious the health condition, the more money is spent on research to cure it. Second, as incomes rise, transfers from the healthy to the ill also increase, most likely through the mechanism of insurance. The technological possibilities for curing bad health expand, and, thanks to insurance, these treatments can be financed. Third, lower mortality rates lead to extra expenditures in the additional years of life. As a result, the constant age profiles of HCEs should cause serious errors in the forecasts.

The relationship of the dynamics of HCEs is much stronger for time-to-death than for age structure. This rise in HCEs over the last $30-40$ years resulted in the concentration of expenditures among those in poor health (close to death) rather than in any specific age group. This finding supports the results of van Baal and Wong (2012) for the Netherlands, who found that HCEs are concentrated before death, and that HCEs grow fastest among those who are close to death. This result is therefore in line with the argument that health insurance fosters transfers from people in good health to people in bad health.

Adopting new, expensive medical technologies leads to increases in life expectancy, but these additional years of life are costly, as Zweifel et al. (2005) showed. The most important implication of the 'red herring' hypothesis-i.e., that ageing has a neutral effect on HCEs-is thus undermined. On the other hand, if the growth in HCEs is concentrated among people who are in bad health but are under age 60 , the main implication of the red herring hypothesis might still be valid, and the rising share of the elderly in the population would very weakly influence HCEs.

Our approach is designed to measure the strength, rather than the cause, of the relationship between HCEs, age, and time-to-death. From our results we cannot definitely say whether higher HCEs lead to lower mortality, or whether HCEs are concentrated before death without having any effect on mortality. The long-term growth in HCEs driven by technological progress in medicine and rising incomes is concentrated among people who are in bad health, and in particular among those who are close to death. Instead of deliberating on the consequences of the past trends, we would like to point out that as fiscal pressures arising from population ageing may be expected to limit HCE increases, the continuation of the process of the concentration of HCEs in the last stages of life seems improbable. Moreover, when the differences in the dynamics between those who are closer to or further from death are restrained, the effects of ageing on HCE should also be limited.
